How does the cerebellum contribute to context-embedded prediction in social and non social scenarios?

Internal models in the cerebellum

Daniel M. Wolpert, R. Chris Miall and Mitsuo Kawato

[The cerebellum as a neuronal prediction machine](#)

[Go to](#)

More than simply a neuronal learning machine, the brain is a prediction machine. Across sensory and motor systems, growing evidence suggests that a key operating principle of the brain is to establish internally generated predictions that can be compared against feedback from the external world in order to guide anticipatory actions and perceptions ([Keller and Müssig-Flogel, 2018](#)).

The cerebellum has long been thought to operate predictively to support motor control and motor learning ([Wolpert et al., 1998](#)). As originally proposed by Masao Ito, the cerebellum is hypothesized to utilize a predictive model that anticipates the expected outcome of motor commands in order to refine future movements ([Ito, 1970](#); [Ito, 1972](#)). Indeed, decades of research have provided considerable support for this hypothesis ([Ohiyama et al., 2003](#)), and revealed many of the circuit pathways ([Apps and Garvicz, 2005](#)) and mechanisms ([Carey, 2011](#)) that allow the cerebellum to predictively modify motor output. However, emerging evidence suggests that the role of the cerebellum in motor control may be more complex than previously appreciated ([Medina, 2019](#)). Moreover, it has also become clear that the cerebellum plays a much wider role in brain function than simply refining movements ([Buckner, 2013](#); [Leiner et al., 1986](#); [Schmahmann, 1991](#); [Sokolov et al., 2017](#); [Strick et al., 2009](#)). Recently, with advances in modern circuit

Abstract

The traditional view on the cerebellum is that it controls motor behavior. Although recent work has revealed that the cerebellum supports also nonmotor functions such as cognition and affect, only during the last 5 years it has become evident that the cerebellum also plays an important social role. This role is evident in social cognition based on interpreting goal-directed actions through the movements of individuals (social “mirroring”) which is very close to its original role in motor learning, as well as in social understanding of other individuals’ mental state, such as their intentions, beliefs, past behaviors, future aspirations, and personality traits (social “mentalizing”). Most of this mentalizing role is supported by the posterior cerebellum (e.g., Crus I and II). **The most dominant hypothesis is that the cerebellum assists in learning and understanding social action sequences, and so facilitates social cognition by supporting optimal predictions about imminent or future social interaction and cooperation.** This consensus paper brings together experts from different fields to discuss recent efforts in understanding the role of the cerebellum in social cognition, and the understanding of social behaviors and mental states by others, its effect on clinical impairments such as cerebellar ataxia and autism spectrum disorder, and how the cerebellum can become a potential target for noninvasive brain stimulation as a therapeutic intervention. We report on the most recent empirical findings and techniques for understanding and manipulating cerebellar circuits in humans. Cerebellar circuitry appears now as a key structure to elucidate social interactions.
